## ABSTRACT

The Hengduan Mountain region is located at the eastern end of the Himalayan range and in the southeastern corner of the Qinghai-Tibet Plateau in eastern Asia. It is probably the richest temperate region in the world biologically, with about 8000 species recorded from the 500,000 km<sup>2</sup> region. A high rate of polyploidy was expected in the Hengduan Mountains because of the unusually high species diversity and endemism, the widespread alpine environment in this region, and the importance of polyploidy in plant evolution. Chromosome numbers for 552 taxa of native Hengduan angiosperms were obtained from published literature. If the criterion of infrageneric polyploidy is used (i.e., the possession of three or more basic chromosome sets in a nucleus), the frequency of polyploidy is only 22%. It is 37% and 58% if taxa with haploid chromosome number  $n = 14$  or more, or  $n = 11$  or more are considered to be polyploids, respectively. Several highly diversified groups such as *Aconitum* and *Delphinium* also show a low proportion of polyploidy (18.6% and 0%, respectively) in the Hengduan Mountains. Examples from other large plant groups (e.g., *Saxifraga*, *Ligularia*, and *Cremnathodium*) and endemic genera (e.g., *Solms-laubachia*, *Tibetia*, and *Nomocharis*) again indicated that polyploidy, especially infrageneric polyploidy, may have played a minor role in the evolutionary diversification of these plants in the Hengduan Mountains.

**Key words:** chromosome number, diversification, Hengduan Mountains, Hotspot, polyploidy.

---

The Hengduan Mountains are located at the eastern end of the Himalayan range and in the southeastern corner of the Qinghai-Tibet Plateau, the highest and youngest plateau in the world. The region comprises more than 500,000 km<sup>2</sup> of temperate to alpine mountains in southwestern China and is bounded in the northwest by the dry Qinghai-Tibet Plateau, in the north by the Tao River of southern Gansu, and in the east by the Sichuan Basin and the plateau of eastern Yunnan. It also includes small portions of extreme northern Myanmar and extreme eastern India. About 8000 species of flowering plants have been recorded from this region (X. W. Li & Li, 1993; W. T. Wang et al., 1993, 1994), making it one of the two most speciose floristic subregions of the Sino-Himalayan Floristic

Region, the other being the East Himalayan subregion (Wu, 1979, 1988; X. W. Li, 1994). The region is also renowned as the home of the giant panda (Wu, 1988). Based on a series of expeditions to the region during 1981–1983 organized by the Chinese Academy of Sciences (Wu, 1988), W. T. Wang et al. (1993, 1994) and X. W. Li and Li (1993) published a preliminary appraisal of the flora that documented its high levels of species diversity and endemism. Although the Hengduan Mountains are still poorly known to the western scientific community, they are biologically among the world's richest and most diverse regions (Boufford & van Dyck, 1999) and have recently been recognized as the biologically richest temperate region in the world, characterized by the occurrence of some of

the world's most distinctive species, such as *Acanthochlamys bracteata* P. C. Kao (Velloziaceae), *Sinodoxa corydalifolia* C. Y. Wu et al. (Adoxaceae), *Salweenia wardii* E. G. Baker (Fabaceae), and *Takakia ceratophylla* (Mitt.) Grolle (Bryophyta). Other floristic characteristics of the range include great regional radiations within a large number of plant groups, and the occurrence of a large number of relict plant lineages (Ying & Zhang, 1984; Wu, 1988; H. S. Wang, 1989; Wilson, 1992; X. W. Li & Li, 1993; Ying et al., 1993; H. S. Wang & Zhang, 1994; Boufford & van Dyck, 1999; H. Sun, 2002a, b; H. Sun & Li, 2003). The area was previously included in the Eastern Himalayan "hot spot" (Myers, 1988; Wilson, 1992), but more recently has been referred to as the South-Central China Hotspot (Myers et al., 2000) or the Hengduan Mountains Hotspot (Boufford & van Dyck, 1999). This Hotspot is a focus for studies of relationships between florogenesis and plate tectonics, on the origins of the north temperate flora, including the floras of eastern Asia, North America, and Europe, and on the evolution of seed plants in general (Wu, 1988).

Polyplody, the possession of three or more basic chromosome sets in nuclei (Bennett, 2004), has long been recognized as a prominent force in the evolutionary diversification of plants (Winge, 1917; Darlington, 1937; Stebbins, 1940, 1950, 1971; Grant, 1981; Levin, 2002), especially ferns (Wagner, 1980; Werth et al., 1985) and flowering plants (Lewis, 1980; Soltis & Soltis, 2000; Wendel, 2000). This phenomenon occurs in up to 80% of all angiosperm species and is considered to be one of the most important cytogenetic mechanisms in plant evolution (Masterson, 1994; Levin, 2002), especially in facilitating rapid speciation (Hiremath & Salimath, 1991).

At the beginning of this research, our working hypothesis was that a high proportion of polyploids occurs in the angiosperm flora of the Hengduan Mountains. Below we outline the reasoning behind this hypothesis and provide a general introduction on the physical and biological characteristics of the Hengduan Mountains Hotspot.

The Hengduan Mountains are geologically young, yet possess an extremely rich flora both in terms of overall species diversity and endemics. The Hengduan Mountains rose relatively rapidly from sea level to the present high mountains (up to 7600 m) with rugged and dissected topography following the collision of the Eurasian and Indian plates about 50 million years ago (Patriat & Achache, 1984; C. S. Wang & Ding, 1998; Tao, 1992, 2000). The most common mechanism for rap-

id speciation in plants is through polyploidy (Grant, 1981). Recent studies in several plant groups have revealed that the genesis of allopolyploidy under both synthetic and natural conditions is often accompanied by rapid genetic and sometimes evolutionarily conserved epigenetic changes (B. Liu et al., 1998; Ozkan et al., 2001; B. Liu & Wendel, 2003; Osborn et al., 2003; Soltis et al., 2004). The capacity of angiosperms to form new combinations via polyploidy may help explain rapid diversification and high endemism in a given region with high biodiversity. Polyploidization might thus account for the high species diversity and endemism in the Hengduan region.

In regions such as the Hengduan Mountains with highly diversified floras, a high frequency of polyploidy would also be expected because of the crucial role of polyploidy in plant speciation (Grant, 1981). Polyploids can have more than two different alleles at any given locus. The intrinsic advantages of heterozygosity may be a key factor in the growth, performance, and adaptability of a polyploid (Grant, 1981; Levin, 1983; Ramsey & Schemske, 1998, 2002; Soltis et al., 2004). Polyploid populations often demonstrate extensive genomic rearrangement including the origin of novel regions of DNA (Song et al., 1995; Arnold, 1997).

Alpine and arctic floras have been reported to have high frequencies of polyploidy (Hanelt, 1966; Löve & Löve, 1967, 1975; Ohba, 1988; Abbott & Brochmann, 2003; Brochmann et al., 2004). Likewise, polyploids are more common in cold climates associated with harsh environmental conditions (Löve & Löve, 1949, 1967). Grant (1981) also suggested that disturbed habitats and stressful environments, which are often associated with cold climates, usually favor polyploidy. The great ecological amplitude that polyploid species can exhibit gives them a high degree of buffering against environmental changes over long periods of time due to glaciation, mountain building and degradation, and overall fluctuations in climate (Stebbins, 1971; Grant, 1981). The Hengduan region has extensive alpine areas. Environmental extremes such as cold and severe climate, and nutrient stress in high latitude or altitude areas have been suggested to increase the frequency of  $2n$  gamete formation (Thompson & Lumaret, 1992; Levin, 2002), which leads to polyploidy.

Polyploids have been suggested to be more adaptive in disturbed or novel niches than their diploid progenitors (Ehrendorfer, 1980; Grant, 1981; Stebbins, 1985; Morton, 1993; Otto & Whitton, 2000; Levin, 2004). The Tertiary Himalayan orogeny has led to changes in the climate and topography of the

Hengduan Mountains (J. J. Li et al., 1995; Shi et al., 1998), whose uplifting and the advance and retreat of ice sheets and glaciers may have provided opportunities for the establishment of polyploids through hybridization and other mechanisms in the contact zones between existing species. The advantages and fitness polyploidy can bestow on organisms will be most effective when new habitats are being created and become available for colonization (Morton, 1993). Ehrendorfer (1980) also surveyed various plant communities to determine polyploid frequency in the flora of lower Austria, and found that the highest proportion of polyploid species was found in disturbed areas.

The objectives of this paper are to: (1) present a comprehensive review of chromosome numbers for the flora of the Hengduan Mountains, (2) calculate the frequency of polyploidy in this region and in exemplar taxa, and (3) test the hypothesis that polyploidy is important in the evolutionary diversification of its rich angiosperm flora.

#### METHODS AND TERMINOLOGY

For each taxon (including species and subspecies), chromosome numbers were recorded from published reports. Several chromosome atlases were also consulted (Darlington & Wylie, 1955; Bolkhovskikh et al., 1969; Moore, 1973, 1974, 1977; Goldblatt, 1981, 1984, 1985, 1988; Goldblatt & Johnson, 1990, 1991, 1994, 1996, 1998, 2000, 2003).

We employed three methods to evaluate polyploids. First, taxa with three or more basic chromosome sets in nuclei are regarded as polyploids (Bennett, 2004), i.e., as resulting from infrageneric polyploidy (Stebbins, 1950). The second method recognizes polyploidy based on the criterion of haploid number  $n = 14$  or more for statistical purposes (Grant, 1963, also see 1981: 296). Goldblatt (1980) suggested a third method, arguing that Grant's (1963) estimate was too conservative, and proposed that taxa with haploid number  $n = 11$  or more should be considered as polyploids. In our study, we have employed all three methods to estimate the incidence of polyploidy in the Hengduan region. We emphasize infrageneric polyploidy in our discussion, because we consider this measure to be the most accurate of the three. We also inferred the ploidal level for each taxon based on Stebbins's (1950) criterion (results shown in Appendix 1). A few taxa with both polyploid and diploid counts are treated as polyploids in our calculation.

In this paper,  $2n$  refers to a taxon's somatic chromosome number and  $n$  to the gametic chromosome

number regardless of the ploidy level, while  $x$  is the most probable base number. The large number of species and the paucity of taxonomic treatments for the study region made it difficult to assign previously published records to currently recognized taxa. We thus report chromosome numbers under the names that were originally published.

#### FREQUENCY OF POLYPLOIDY IN THE HENGDUAN MOUNTAINS

Chromosome counts for 552 species and infraspecific taxa in 152 genera and 44 families from the Hengduan Mountains are shown in Appendix 1. Most taxa are representatives of genera that are taxonomically diversified and ecologically common in the region, such as *Rhododendron*, *Silene*, *Armenia*, *Rubus*, *Ligularia*, *Delphinium*, *Poa*, *Astragalus*, *Saussurea*, *Aconitum*, *Primula*, *Gentiana*, and *Pedicularis*, all of which are characterized by regional radiation. Others, such as *Acanthochlamys*, *Beesia*, *Circaeaster*, *Dichotomanthes*, *Kingdonia*, *Nomocharis*, *Pomatosace*, *Przewalskia*, *Salweenia*, *Solms-laubachia*, and *Souliea*, are largely endemics to the region. At present no chromosome counts are available for certain large families, such as Lamiaceae, Cyperaceae, and Crassulaceae.

When polyploidy is calculated based on three or more basic chromosome sets in nuclei recorded in a genus (infrageneric polyploidy), only 22% (124/552) of the angiosperm taxa sampled in the Hengduan Mountains are polyploids. Using this same method, 30%–35% are estimated to be polyploids for all flowering plants whose chromosome numbers have been counted (Stebbins, 1950) and 36% for monocots (Goldblatt, 1980: 225).

Based on the criterion that haploid number  $n = 14$  or more denotes polyploidy sensu Grant (1963, 1981), 37% (204/552) of the angiosperm taxa from the Hengduan Mountains are polyploids (Table 1). These values are relatively low compared with previous estimates. Grant (1963) reported that 47% of the 17,138 species of flowering plants he sampled were polyploids. According to the method of Goldblatt (1980) with  $n = 11$  or above as polyploids, 58% (322/552) of the angiosperm taxa in the Hengduan region are polyploids. Using the same criterion, Goldblatt (1980) reported that 68% of the 10,580 species of monocots he surveyed were polyploids.

#### COMPARISONS WITH OTHER REGIONS

Because of the limited sample size of our chromosome data (ca. 6.9% of the estimated 8000 species present in the Hengduan Mountains), we com-

Table 1. Polyploidy statistics of angiosperms in the Hengduan Mountains based on three methods: (a) infrageneric polyploids—taxa with three or more base chromosome number sets (Stebbins, 1950; Bennett, 2004); (b) haploid number  $n = 14$  or more (Grant, 1963); (c)  $n = 11$  or more (Goldblatt, 1980).

	Total species (%)	Infrageneric polyploidy Species number (%)	Polyplody ( $n \geq 14$ ) Species number (%)	Polyplody ( $n \geq 11$ ) Species number (%)
All species sampled	552	124 (22)	204 (37)	322 (58)
Endemic species	183 (33)	29 (16)	49 (27)	89 (49)

pared our findings with chromosome data for the plants of Pakistan. Pakistan is located on the western end of the Himalayan range. The chromosome data from Pakistan are based on a larger sample size, i.e., 1777 species and infraspecific taxa sampled (34% of its total angiosperm flora). As shown in Table 2, the frequency of polyploidy in Pakistan is similar to what we found for the Hengduan Mountains, with 29% infrageneric polyploidy, and 44% ( $n = 14$  or more) or 63% ( $n \geq 11$ ) based on the two methods for estimating polyploidy, as calculated using data taken from Khatoon and Ali (1993). The similar incidence of polyploidy in these two regions may reflect a broader characteristic of polyploid distribution in the Himalayan range. Although the sample size in our study includes only a small proportion of the angiosperm flora of the Hengduan Mountains, it nevertheless provides good taxonomic and ecological representation. The available data suggest that the flora of the Hengduan Mountains is characterized by a relatively low frequency of polyploidy.

As indicated above, the frequency of polyploidy is higher in arctic floras than those at lower latitudes (Hanelt, 1966; Löve & Löve, 1975; Abbott & Brochmann, 2003). The frequency of polyploid species in the vascular flora of the arctic region as a

whole is nearly 60% in the low arctic zone, but 70% in the high arctic and as high as 80% in high-arctic endemics (Löve & Löve, 1975). Brochmann and Steen's (1999) research on the isolated arctic archipelago of Svalbard, which was almost completely ice-covered during the last glaciation, showed that nearly 80% of the 161 native species are polyploids. A recent review on arctic plants based on 1719 taxa showed that the majority (60.7%) are polyploids, especially for arctic specialist taxa (73.7%) (Brochmann et al., 2004).

Löve and Löve (1967) pointed out that the frequency of polyploidy is significantly high in the alpine zone, as on Mt. Washington in the White Mountains of New Hampshire, where 63.6% of the alpine taxa of vascular plants are polyploids. Another example is from the flora of the Cameroon Mountains (Morton, 1993), which shows a frequency of 52.9%, higher than generally reported (sensu Grant, 1981). Hanelt (1966) gave percentages ranging from 45% to 85% polyploids in various high mountain floras in Eurasia, the Americas, and New Guinea.

Our finding of only 22% polyploidy in the angiosperm flora of the Hengduan Mountains based on the same method of calculation (Stebbins, 1950) stands in sharp contrast with these earlier results.

Table 2. Comparison of frequency of polyploidy among selected regions or plant groups.

	Reference	Infrageneric polyploidy, %	Polyplody ( $n \geq 14$ ), %	Polyplody ( $n \geq 11$ ), %
Hengduan Mountains		22	37	58
Pakistan	Khatoon & Ali (1993)	29	44	63
Monocots	Goldblatt (1980)	36		68
Angiosperms	Stebbins (1950)	30–35		
	Grant (1963, 1981)		47	
High mountain floras	Hanelt (1966)	45–85		
Cameroon Mountains	Morton (1993)	52.9		
Mt. Washington	Löve & Löve (1967)	63.6		
Arctic flora	Löve & Löve (1975)	60–80		
Svalbard	Brochmann et al. (2004)	60.7		
Juan Fernandez Islands	Brochmann & Steen (1999)	ca. 80		
Hawaii	Sanders et al. (1983)		75	
	Carr (1998)		80	

A similar survey on Chihuahuan Desert flora showed that a relatively low frequency of 17.8% polyploidy occurs among the gypsophilic species compared to 32.7% polyploidy for the non-gypsum vegetation (Powell & Sloan, 1975). Further chromosome reports on some species from the Hohxil region of Qinghai, a harsh, cold, uninhabited, alpine desert at an average elevation of 5000 m near the center of the Qinghai-Xizang Plateau, also showed that most plants there are diploids (Y. P. Yang & Wu, 1993).

Several studies using the more inclusive criterion that taxa with gametic numbers of  $n = 14$  and above are regarded as polyploids (Grant, 1963) have found higher levels of polyploidy than the 58% we estimated for the Hengduan region. For example, Sanders et al. (1983) reported 75% polyploidy for the flora of the Juan Fernandez Islands, and Carr (1998) reported 80% for Hawaiian plants.

#### POLYPLOIDY IN REPRESENTATIVE TAXA

We expected to find a high level of polyploidy before we began this study, but it seems that polyploidy is not common in the Hengduan Mountains based on regional cytological statistical comparisons. This result is even more pronounced when one considers the frequency of polyploidy in several representative taxa from the Hengduan Mountains Hotspot.

#### HIGHLY DIVERSIFIED GROUPS

*Aconitum* and *Delphinium* are two closely related genera of Ranunculaceae in the tribe Delphineae and are widely distributed in north temperate areas. About half of the species of *Aconitum* and more than 63% of the species of *Delphinium* are found in the Hengduan Mountains (Q. E. Yang et al., 1989). The species in these two genera are highly diversified in the region, with both primitive and advanced representatives, including many local endemics (X. W. Li & Li, 1993; Q. E. Yang, 1996). The cytological data reveal that of 43 species in *Aconitum* in the Hengduan region (41% of the total 104 species), 30 are endemic to the area, and only eight are polyploids (18.6%). There are no polyploids among the 23 species (11 endemics) of *Delphinium* reported (32% of the total 71 species in the region). However, in Simon et al.'s (1999) comprehensive chromosome survey of Delphineae, which included about 40% of species in the tribe, 48% and 31% of *Aconitum* and *Delphinium* species were found to be polyploids, respectively. These figures are much higher than our estimates from the Hengduan region. The high diversity of these gen-

era in this region has resulted mainly from speciation within diploid lineages.

*Ligularia* and *Cremanthodium* (Asteraceae) are two related genera that are also highly diversified in the Hengduan Mountains (Liu, 2004). *Ligularia* has 129 species in the region, with about 100 native and 60 endemic. This genus is morphologically diverse and has members in a variety of habitats, from forests to high alpine meadows, ranging from 1000 to 4000 m in altitude, although most species are found in the mountains (S. W. Liu et al., 1994). *Cremanthodium* comprises 67 species growing in alpine meadows, largely in the Hengduan Mountains and on the Qinghai-Tibet Plateau. Although these genera do not qualify for Stebbins's (1950) definition of infrageneric polyploidy, their high haploid chromosome numbers of  $n = 30$  and  $n = 29$  suggest ancient polyploidizations. Variation of karyotype structure at the diploid level seems to be the predominant feature in these groups, and sympatric speciation via hybridization and polyploidization has played a minor role in their species diversity (J. Q. Liu, 2004).

A similar phenomenon can be seen in several other groups occurring around or within the Himalaya and Qinghai-Tibet Plateau. *Saxifraga* (Saxifragaceae) is widely distributed in the temperate zone of the Northern Hemisphere and is one of the most important components of the alpine flora of the Himalayan region (Ohba, 1986). In particular, some species are quite diverse in the high alpine region of the Himalaya as well as in the Hengduan Mountains. In the Hengduan Mountains, four of the nine species reported are polyploids (44.4%). However, cytological studies of *Saxifraga* in the Himalayas by Wakabayashi and Ohba (1988) showed that diploids prevail and polyploids comprise only 17% of the species. Polyploidy thus may not have played an important role in the diversification of *Saxifraga* in the Himalayan range (Wakabayashi & Ohba, 1988).

#### ENDEMIC TAXA

High levels of endemism are a major feature of the flora of the Hengduan Mountains. About 37.7% of the angiosperms are endemic or mainly restricted to this area (X. W. Li & Li, 1993). Of the 552 taxa sampled, 33% are endemic to the Hengduan region (Table 1), a proportion similar to that of the total angiosperms in the region. But infrageneric polyploidy is particularly low among endemics (just 16%). Below we discuss several endemic genera to illustrate this phenomenon.

The nine species of *Solms-laubachia* (Brassicaceae)

ceae) are nearly restricted to scree slopes and rocky crevices at altitudes of 3400–5700 m in the Hengduan Mountains (Al-Shehbaz & Yang, 2001; Yue et al., 2004). All species are  $2n = 14$ , although one species (*S. pulcherrima* Muschl.) has a tetraploid cytotype (Yue et al., 2003, 2004). Speciation within *Solms-laubachia* may have been the result of primarily intrachromosomal variation at the diploid level, and the genus probably evolved within the Himalayan-Hengduan Mountains instead of migrating from other regions (Yue et al., 2004).

Another example is the small, localized, nearly endemic genus *Tibetia* (Fabaceae). This genus apparently differentiated from the widely distributed north temperate *Gueldenstaedtia* and became adapted to the alpine environment (Tsui, 1979; Nie et al., 2002) as the Hengduan Mountains uplifted. The cytological studies of Nie (2002), Nie et al. (2002), and D. K. Yang (2002) show that the species of *Tibetia* have all evolved at the diploid level of  $2n = 16$ , but with alterations of their karyotypes. These authors suggest the importance of allopatric speciation at the diploid level in *Tibetia* in the Hengduan Mountains.

*Nomocharis* (Liliaceae), comprising ca. 10 species with the Sino-Himalayan distribution pattern, is restricted to the Hengduan Mountains and the southeastern edge of the Tibetan Plateau. All its members are not infrageneric polyploids, with  $2n = 24$ , and appear to have diversified at the diploid level after ancient polyploidization (Xie et al., 1992). Other taxa, such as *Salweenia* (Q. X. Zhou et al., 2000), *Beesia* (Q. E. Yang et al., 1995), and *Kingdonia* (Z. Y. Zhang, 1982), are likewise all diploids that have developed and become localized in the Hengduan Mountains area.

#### EVOLUTION OF HIGH SPECIES DIVERSITY IN THE HENGDUAN MOUNTAINS HOTSPOT

If polyploidy did not play a major role in the evolution of Hengduan plants, what other mechanisms might have shaped the substantially high species diversity and endemisms in the region? Below we propose a few hypotheses based on physical and historical factors.

Alpine plants survive under the environmental conditions they encounter because of adaptive features such as cushion or rosette habit, pubescence, and coriaceous leaves (Chaverri-Polini, 1998; Körner, 2003). Morphological differentiation can be accumulated in a relatively short period under certain alpine environments through natural selection, without drastic genetic or chromosomal divergence. For example, *Sinodoxa*, an endemic monotypic ge-

nus of Adoxaceae from the Hengduan region, is closely related to *Adoxa* (J. Q. Liu et al., 2000b), but is morphologically very distinct, despite low ITS sequence divergence (3.4%), which suggests a recent origin of *Sinodoxa*. Both genera have the same chromosome number of  $2n = 36$  and a similar karyotype, and the initial differentiation between them might have resulted from allopatric isolation when the first large-scale uplifting of the Qinghai-Tibet Plateau occurred about 3.4–1.7 million years ago (J. Q. Liu et al., 1999, 2000b).

Geographical and ecological heterogeneity may have played an important role in the diversification of plants in the Hengduan Mountains. Most parts of the region are characterized by a series of parallel mountain ranges dissected by deep river valleys that run from north to south, which present physical barriers to gene flow. The high speciation rate in the Hengduan flora may also be due to highly varied local climates that result from geographic differences in the mountains. The wide diversity of climates combined with local differences in geomorphological, edaphic, and ecological features may have generated distinct niches for different species. *Rhododendron* (Ericaceae), for example, is the largest genus in the region with about 220 species extending throughout the Hengduan area, but most species have highly localized distributions. Both diploids and polyploids are common among *Rhododendron* in the Hengduan Mountains, with a high base chromosome number of  $x = 13$  (Darlington & Wylie, 1955; Gao, 2002). The radiation of *Rhododendron* in this region is perhaps related to geographic heterogeneity in conjunction with polyploidy.

Animals such as insects may have played a vital role in the dispersal as well as the evolution of reproductive isolation of some groups in the region. *Pedicularis* is a circumpolar genus of Scrophulariaceae, consisting of approximately 500 species, with about 200 occurring in the Hengduan Mountains, making it the second largest genus of angiosperms in the region (X. W. Li & Li, 1993). *Pedicularis* shows extreme variation in floral morphology that is correlated with specific mechanisms of pollination involving a diverse group of insects. Chromosome numbers of *Pedicularis* recorded in the Hengduan Mountains are  $2n = 14$  and 16 (J. Cai et al., 2004), suggesting that the evolution has taken place at the diploid level and that diversification is perhaps facilitated by the behavior of pollinators.

Climatic changes during the Pleistocene glacial and interglacial periods may have resulted in the formation of many refugia in the region; these re-

fugia may have served as shelters for a rich diversity of species, as well as sources for dispersion to neighboring areas during the warm interval. The arctic and Tethyan Tertiary floras also served as a source of the floristic development of the region, with the existence of migration routes for plants from the north to the south and vice versa (H. Sun, 2002a, 2002b; H. Sun & Li, 2003).

#### CONCLUSIONS

Polyplody (especially infrageneric polyplody) is not common in the alpine flora of the Hengduan Mountains Hotspot based on our cytological statistical analysis. This finding is further strengthened by case studies of representative taxa in the region. High levels of speciation activities in the Hotspot are probably attributable at least in large part to the geographic, climatic, and geological heterogeneity that resulted from the Tertiary Himalayan orogeny and Cenozoic ice-age cycles. Further investigations, particularly of taxa characteristic of the area, are needed to (a) further test our findings of low frequency of polyploids in the Hengduan region in a phylogenetic framework, (b) examine other prominent evolutionary forces involved in speciation in the Hotspot, and (c) explore the possible reasons for the apparently low rate of formation and/or survival of polyploid species. We hope this cytological study will stimulate further chromosomal and evolutionary work on the Hengduan Mountains Hotspot, and on other conservation hotspots as well.
